Frequently a technological advancement is introduced in military systems with benefits so great that little effort is expended to optimize its use by human operators. Sometimes even serious limitations are not investigated because the device adds such obvious improvement to mission performance. This is the case with the night vision goggle (NVG) image intensifiers currently used by United States Army and Air Force Military Airlift Command (MAC) rescue personnel. Although the goggles are normally used when the human operator's visual capabilities are unimpaired, they are also worn by mountain search team members and aviators. Limits

of use have not been established, nor do we have sufficient understanding of the effects of mild hypoxia on visual performance with NVGs to establish such limits objectively.

→ Pilots have frequently reported an apparent darkening of the visual field while flying at high altitude without supplemental oxygen, and subsequent exposure to oxygen resulted in marked increases in the brightness of lights. (Goldmann & Schubert, 1933).

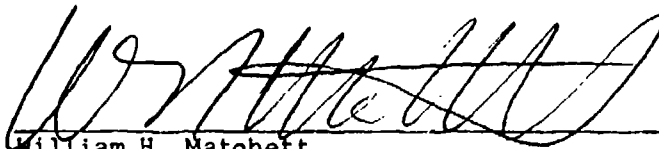

✓ Likewise, at low light intensities visual acuity is greatly decreased during oxygen deprivation. (McFarland & Halperin, 1940).

✓ In contrast, at high light intensities, the effect of moderate oxygen deprivation on visual acuity is slight. Even though the

~~Night Vision Goggles~~
✓ NVGs amplify low night illumination, the interaction between amplified illumination and high altitude effects may prove to be important factors in visual performance.

The objective of this research was to investigate the effects of mild hypoxia on monocular visual performance with NVGs. This study revealed that mild oxygen deprivation significantly affects unaided square-wave grating visual acuity but does not significantly affect NVG-augmented performance. Large differences between visual sensitivities at different spatial frequencies were not differentially affected by mild hypoxia. Supplemental oxygen did significantly improve naked-eye but not NVG-augmented night resolution acuity up to an altitude of 13,000 feet (3,962 m) above sea level (ASL).

"Mild Hypoxia and Visual Performance with Night Vision Goggles,"
a thesis prepared by Leray Lyle Leber in partial fulfillment of
the requirements for the degree, Master of Arts, has been approved
and accepted by the following:

William H. Matchett
Dean of the Graduate School

Chairman of the Examining Committee

4 February 1985

Date

Committee in charge:

Dr. Stanley N. Roscoe, Chairman

Dr. Darwin P. Hunt

Dr. Hans Marmolin

Dr. G. Morris Southward

Acknowledgements

A number of persons and organizations made contributions to this investigation.

Dr Stanley Roscoe rendered invaluable assistance in my background search, investigation formalization, proposal defense, and manuscript preparation. Dr. G. Morris Southward provided invaluable statistical advice and computer interface assistance.

The cooperation of personnel at Kirtland AFB was most appreciated. The Base Hospital, 1550th Combat Crew Training Wing, and Air Force Weapons Laboratory made me more than welcome and provided workspace, technical assistance, and personnel support. Although there were many people in these organizations who helped with advice and assistance, I direct special thanks to:

Col Frederic Brown, Col Floyd E. Hargrove, Col Norman Le .
Maj James Route, Mr. Wayne Wasson, Maj E. A. Silver, M.D.,
Capt Scott Rice, M.D., MSgt Gerald McCullough, and each of
my volunteer observers.

I thank my previous Air Force command for their assistance and encouragement. Much laboratory and expert guidance was coordination through Major Mike Marquart, Test and Evaluation Division, Military Airlift Command Headquarters.

My list of names, phone numbers, and addresses of those who helped me from project conception to this report is very long. I hope all who answered, helped, or directed me to those who could will accept my thanks; and to them all I am indebted.

Introduction

Night Vision Goggles

The AN/PVS-5 night vision goggle system (Figure 1) is a 1.9-pound, battery-operated, self-contained, head-mounted (helmet-mounted for aviators) binocular system that both intensifies and augments existing light. Photocathode optics using the P20 phosphor provide a grainy greenish tint to all viewed objects within their 40-degree field of view. Goggle spectral response of 360 to 900 nm (Figure 2) is more sensitive to infrared radiation than the normal human visual response of 400 to 700 nm (Jensen, 1981). An internal infrared-emitting diode provides supplementary illumination for close-range viewing when external light is not available. The binocular system has independently adjustable focus for each monocular lens, allowing focus between 15 inches (38.1 cm) and optical infinity.

Figure 1. AN/PVS-5 night vision goggle system.

The goggles were originally designed to provide their wearers with improved night vision for reading, performing manual tasks, patrolling, medical aid, construction work, mobile equipment operation, driving, walking, air support, and surveillance using starlight and moonlight from the night sky. They provide unity magnification, with viewing range approximately 150 m for man-size targets and 350 m for vehicle-size targets. The NVGs require a 2.7 volt d.c. power supply, and the life of their single 3/4-inch round battery is 12 hours. Their ambient temperature operating limits allow use between -65 and 125 degrees Fahrenheit. Today, the NVGs are routinely worn by Army and MAC ground party searchers, pilots, aircrew members, and scanners (searchers) aboard aircraft.

The NVGs incorporate variable gain light amplification and

Figure 2. NVG sensitivity and night sky irradiance.

thereby affect the conditions under which an operator can perform visual tasks. For example, they transform scotopic conditions, an environment with ambient starlight illumination (10^{-4} cd/m²), into comfortable-reading, mesopic conditions (1 cd/m²). Thus, the NVGs change the retinal stimulation from a state in which rods dominate visual detection and resolution to one in which both rods and cones contribute in visual performance. Although the NVGs offer a significant improvement over vision with the naked eye, the use of NVGs creates a different visual environment, one that may involve deleterious side effects.

Visual Performance

Spot detection threshold. The primary stimulus for vision is the absorption of light by retinal photoreceptors. Detection studies have shown that only a few quanta of light are needed for detection with scotopic or rod vision in ideal conditions (Bouman & van der Velden, 1947, plus an extensive bibliography by Davson, 1962). Sometimes there is a distinction made between search detection and threshold detection, the former entailing a local search task, whereas the latter refers to the presence of a stimulus in a fixed location made known to the observer prior to introduction.

Any surface or volume that emits radiant energy is a source. Every source has finite size, but when its size is small compared with its distance to the observer, it is called a point source. A point source is usually produced by placing a pinhole before a lamp or other light source. Detecting a point source is the successful

determination of whether the source of light is present in the visual field. Detection does not require the observer to recognize (name), resolve (recognize as whole or sectioned), or localize (designate with a "position" response) any aspect of the point source.

The intensity or amount of energy required for visual system detection is determined by four major factors:

1. spatial layout
2. state of visual adaptation
3. exposure duration
4. wavelength

Hecht, Shlaer, and Pirenne (1942) attempted to control these conditions to determine a human's maximum sensitivity. They found that a minimum light intensity of 100 quanta was required for spot detection. Each of these characteristics plays a role in detection tasks.

Retinal locus. The receiver surface of the retina is extremely heterogeneous. In daylight conditions, maximum visual acuity is achieved when an image falls on the fovea. When the image falls only on the fovea, vision is referred to as central; otherwise it is lateral or peripheral. The location of a lateral projection is expressed by its eccentricity: the angle between the point of fixation and the center of the test object. Vision is parafoveal when the eccentricity is within 4-5 degrees, perifoveal between 4-5 and 9-10 degrees, and then peripheral.

Adaptation. On passing from strong sunlight into a darkened room, one has difficulty seeing until time passes and the eyes adapt to the state of lower illumination. In a relatively short time the intensity of light necessary for visual perception is noticeably decreased. The decrease in threshold with time in the dark is termed dark adaptation. A typical dark adaptation curve has one discontinuity that indicates the shift from day, or cone-dominated, vision to night, or rod-dominated, vision (Hecht, 1934). This 25- to 30-minute process for gaining fairly complete dark adaptation is progressively impaired with increasing oxygen deprivation (McFarland & Evans, 1939). The effects are thought to be caused by the influence of an oxygen deficiency on both the retina and the central nervous system.

The visual system changes when light levels change from the photopic range of 10^2 to 10^7 cd/m² to the scotopic range of 10^{-6} to 10^{-1} cd/m². Under scotopic (low light) conditions, the cones do not have sufficient sensitivity to function and, consequently, scotopic functioning depends almost exclusively on the more sensitive rod receptors. When the eye is fully dark adapted, the fovea is far less sensitive to stimulation than regions of the periphery (Hecht, Haig, & Wald, 1935).

Since the rod system is responsible for maximum sensitivity, location-specific variation to minimal amounts of light across the retina is primarily (though not entirely) determined by the density of the rods (Cornsweet, 1970). Spot detection sensitivity is greatest at about 10 degrees of eccentricity. Thus, when searching

for a point source of illumination in conditions of low illumination, a person should look a bit to one side.

Stimulus integration. The retina sums quanta over both time and space. Bloch's Law, dealing with the reciprocal temporal relationship between the product of luminance at detection threshold (L) and duration of stimulus (t), is expressed as L times t is equal to a constant. This relationship holds for spot flash durations up to 100 milliseconds for peripheral flashes (scotopic conditions), and 10-20 milliseconds for foveal flashes (photopic conditions).

The reciprocal space relationship between the area (A) of the spot and the minimum luminance required for threshold detection (L) is Ricco's Law: A times L is equal to a constant. When many rods converge on a single ganglion cell, the activity level of that optic nerve fiber is the same (barring inhibition) whether all the light quanta are absorbed by a single rod or captured by many rods that pool their stimulation. But if the stimulus quanta fall on an area of rods larger than a single ganglion pool, then some of the possible stimulation is lost to other ganglia, and detection threshold may not be achieved.

Spectral sensitivity. Wavelength is an important factor affecting the detection of a point source. The rod receptors for a dark-adapted eye are unequally sensitive to different wavelengths of light (Cornsweet, 1970). The spectral sensitivity function for dark-adapted rod receptors (Wald, 1945) indicates that when monochromatic light (light within a narrow range of wavelengths) is

presented to the eye, a 510 nm (green) stimulus requires the fewest quanta to be detected. The visual system sensitivity difference between 510 nm wavelength light and very long (red) or very short (blue) wavelengths is over a millionfold.

Resolution acuity threshold. Visual acuity is the capacity to discriminate the fine details of objects in the field of view. Measures of acuity test the resolving power of the eyes by determining the smallest spatial pattern or the smallest detail of a pattern that can be recognized as whole or sectioned. The spatial pattern in such tests is usually black on white. The contrast or difference in luminance between the black and white areas is typically made as great as possible.

In a visual acuity task, the size of the test pattern is reduced until its critical detail is no longer resolvable. This requires a frequency-of-seeing determination, and the threshold size is most commonly stated as the visual angle of the pattern detail that can be correctly detected 50 percent of the time. Visual acuity, or decimal acuity, is the reciprocal of the threshold when the latter is expressed in minutes of arc. Normal acuity, 1.0, is the ability to resolve a pattern whose critical dimension subtends 1 minute of arc.

Acuity tests. In aircrew physical examinations, as in most clinical applications, visual acuity is tested with either the Snellen Chart or the Landolt C test. The Snellen Chart contains rows of letters of the alphabet subtending decreasing visual angles. Invented by Snellen in 1862, it has since been

standardized by Sloan (1951). The Landolt C, or ring, is a broken circle with a stroke thickness and gap width one-fifth its outer diameter. Invented by Landolt in 1889, the rings have since been standardized by Shlaer (1937). A subject's resolving abilities have been confirmed once they discern 50 percent of the letters of one size on the Snellen Chart or correctly identify the orientation (direction of the gap opening) for 50 percent of the Landolt C's of a given size.

In 1956, Schade pioneered the use of spatial frequency as an experimental variable in grating detection and resolution tasks to assess visual performance. Each grating is a repeated sequence of light and dark bars. The width of one light bar and one dark bar of a grating is one cycle, or the period of the grating. The reciprocal of the period is the spatial frequency. Spatial frequency is expressed by the number of cycles of the grating that occur per degree of visual angle (cpd). Detection and resolution of a spatial frequency pattern are nearly synonymous; once a stripe pattern is detected, its fine detail or spatial pattern is recognized.

Ginsburg (1981) argues that the Snellen and Landolt standards assess only a small portion of an observer's true visual capabilities and limitations, because they are sensitive to only the highest spatial frequency range (resolving gaps of very small visual angle). Yet degradation in operator performance may occur from poor resolution (low contrast sensitivity) at lower spatial frequencies.

Variables affecting acuity. Acuity is affected by both target and observer variables (Westheimer, 1972). Target variables include retinal location, orientation, contrast, luminance, exposure duration, and wavelength. Observer variables include pupil size, degree of adaptation, and refractive error. The focusing abilities of aircrew members are tested as a part of their annual physical examinations. Military pilots who display marginally poor accommodation are fitted with corrective lenses and allowed to continue flight operations if normal accommodation can be restored with augmentation.

Acuity in a Landolt-ring vision task depends on both the luminance of the background on which the dark target is superposed and the contrast between the target and background. The relationship between intensity of illumination and acuity for Landolt rings was plotted by Shlaer (1937). Expressed logarithmically, acuity increases as a negatively accelerating function of log intensity. The curve has a discontinuity as intensity increases to the level at which the cone (photopic) detection threshold is exceeded. Maximum foveal acuity is maintained over a wide range of higher intensities (Brown, Graham, Leibowitz, & Ranken, 1953).

At higher levels of illumination (photopic conditions), acuity is maximized when the target is viewed with the center of the fovea. There is a significant drop in acuity when the image is displaced within the fovea (Miller, 1961) and a further decrease when the image is progressively displaced in the periphery. The

relationship between photopic acuity and stimulus eccentricity is generally consistent with cone concentration. However, there is evidence against such a similarly direct proportionality between scotopic acuity and rod concentration. When illumination is dim (scotopic conditions), acuity is highest for images located 4 degrees from the fovea, not 20 degrees where the greatest rod density exists (Mandelbaum & Sloan, 1947).

The size of the pupil affects resolution in two antagonistic ways. As the pupil increases in size, it improves acuity by both allowing more light to reach the retina and lessening edge diffraction. Yet, this larger opening lessens the sharpness of the resultant image on the retina due to geometric and chromatic aberrations and focus error caused by light rays passing through the lens progressively further from its center. Several investigators have shown that the best image is obtained with a pupil diameter between 2 and 4 mm (Campbell & Gubisch, 1956; Krauskopf, 1962; Westheimer & Campbell, 1962).

Among the various effects of the spectral composition of illumination, narrow bands of illumination produce the best minimum-visibility and vernier acuities and reduce chromatic aberration (Baker, 1949; Shlaer, Smith, & Chase, 1942, respectively). However, Landolt-ring acuity shows no difference with narrow-band or wide-band illumination (Shlaer et al., 1942). When narrow bands are used in low-intensity illumination, wavelengths must be conditionally adjusted for photopic or scotopic sensitivity for acuities to be equal.

Another factor affecting night augmented focus is the NVG itself. All imaging systems, whether real or virtual, cause eyes to lapse toward their dark focus, or resting accommodation distance (Hull, Gill & Roscoe, 1982; Randle, Roscoe, & Petitt, 1980; Roscoe, in press). This shift causes both myopia, focusing too near, and micropopia, a decrease in apparent size. Each of these effects would be expected to influence threshold detection slightly and target resolution appreciably.

Hypoxia

When airmen or mountain climbers ascend to high altitudes, changes take place in the environment that significantly influence their performance and well-being. The most important feature of high altitude is a reduction in barometric pressure. Air contains oxygen along with nitrogen, carbon dioxide, and traces of rare gases at a total pressure of 760 mm Hg at sea level. Each gas exerts a partial pressure proportional to its volume. Table 1 shows that a reduction in the total barometric pressure with ascent corresponds to a reduction in available oxygen (McFarland, 1953).

Physiological and psychological effects. The common term used to refer to lack of oxygen is hypoxia. A reduction of available oxygen results in a wide variety of physiological and psychological effects dependent on the amount and duration of deprivation. In a state of hypoxia the oxygen available to the cells is inadequate to fulfill their energy requirements. Hypoxia can result from an inability of the cells to use oxygen at a normal rate as well as from insufficient delivery. A simplified classification of hypoxia

Table 1

Physical Characteristics of the Standard Atmosphere

is presented by Van Liere and Stickney (1963):

Anoxic - lack of oxygen in the arterial blood

Anemic - normal blood oxygen tension, but a shortage of functioning hemoglobin

Stagnant - normal oxygen content, but inadequate transfer to the tissues

Histotoxic - some cells are poisoned and unable to use oxygen

Hypoxia is characterized by an increase in rate and amplitude of respiration. According to Slonim (1974), the breathing increase is an almost immediate response to the decrease in arterial partial pressure of oxygen sensed by the carotid and aortic-body chemoreceptors. These compensatory mechanisms serve to counteract the effect of an oxygen deficit by more efficient activity of the cardiorespiratory system. Other physiological adjustments in response to acute hypoxia include the following:

- increased pulmonary ventilation, which increases alveolar partial pressure of oxygen and improves the oxygenation of blood flowing through the pulmonary capillaries
- increased cardiac output, caused mainly by increased heart rate
- selective redistribution of blood flow favoring the heart and brain
- increased ease of oxygen unloading in tissue capillaries from operation in the steep portion of the oxyhemoglobin dissociation curve.

Extended exposure at higher than normal habitation altitudes

results in increased production of red blood cells and automatic physiological effort to combat the lack of oxygen. However, this process occurs relatively slowly and cannot compensate for sudden extended exposures. As the degree and duration of hypoxia increase, the symptoms might progress as follows: headache, lack of attention, mental confusion, drowsiness, disturbance in vision, muscular weakness, and incapacitation (Slonim, 1974).

Human beings may survive through long periods of oxygen deficit if the degree of hypoxia is not too great. However, hypoxia still may cause marked behavioral changes. Barcroft found that beyond 15,000 feet (4,572 m) ASL, severe hypoxia often induces an alcoholic intoxication-like state of euphoria, self-satisfaction, and grossly distorted sense of reality (cited in Van Liere & Stickney, 1963). Both the short-term physiological and behavioral effects experienced at altitudes up to 20,000 feet (6,096 m) ASL are quickly reversed by breathing 100 percent oxygen.

Hypoxia causes drastic and easily recognizable deterioration in performance at altitudes close to the limit of human consciousness. A great deal of research has been directed to this topic, but the bias has been toward manual control tasks that treat the human operator as the physical manipulator of a mechanical system. Yet, it has been known for some time that certain predominantly mental tasks appear to be degraded by hypoxia at exposures to real and simulated altitudes below 10,000 feet (3,048 m) ASL.

Vision decrements. Of all the oxygen users in the body, nervous tissue is the least capable of withstanding deprivation. The brain requires a continuous supply of adequately oxygenated blood to operate at peak efficiency. Billings (1973) indicated that the brain and associated sensory apparatus (especially the retina of the eye) have the highest oxygen uptake per unit mass of any system of the body. While the nervous system accounts for approximately 2 percent of body mass, it uses 20 percent of inhaled oxygen at rest. Krause (1934) showed that because the retina is anatomically a part of the brain, it likewise functionally suffers from oxygen deprivation.

In a discussion of visual accommodation, Simonelli (1980) suggests that visual performance is influenced by subtle environmental conditions that affect the eye's accommodative responses. Stressors such as sudden jolts and loud noises, as well as elevated mental workloads, have been associated with an outward shift in accommodation, while anesthesia and vestibular stimulation are associated with an inward shift. The stress caused by hypoxia would also be expected to bias accommodation, but evidently its specific effects have not been measured and reported.

Fisher and Jongbloed (1935); Hecht, Schlaer, and Pirenne (1942); McFarland (1937, 1938); and Wald (1942) have all shown that hypoxia raises detection thresholds for both light- and dark-adapted eyes. McFarland and associates (1939, 1940) reported a decrease in visual sensitivity at a simulated altitude of only 7,400 feet (2,255 m) ASL; visual sensitivity and dark adaptation

were impaired at altitudes as low as 4,500 feet (1,371 m) ASL; and at 12,000 feet (3,658 m) ASL there was a decline to 60 percent of the sea-level visual acuity. Halperin, McFarland, Niven, and Roughton (1959) noted that although exposure to altitudes between 7,000 feet (2,134 m) ASL and 20,000 feet (6,096 m) ASL changed visual sensitivity these effects were reversed within a few minutes by inhalation of 100 percent oxygen.

For any high-altitude task requiring resolution acuity, the interaction between stimulus intensity and hypoxia is critical. Although at higher illuminations there is little or no impairment in vision at altitudes below 18,000 feet (5,486 m) ASL, under reduced illumination, a decrease in the ability to resolve a given target has been found as low as 8,000 feet (2,438 m) ASL (McFarland & Halperin, 1940).

The Army and MAC Rescue Services are both aware of the effects of hypoxia on mission performance and safety. In addition to extensive initial and periodic refresher training in hypoxia symptom recognition, both services have published regulations aimed at lessening aircrew exposure to hypoxic conditions. Neither service allows its aviators to fly aircraft above 13,000 feet (3,962 m) ASL without supplemental oxygen. Flight between 10,000 feet (3,048 m) and 13,000 feet (3,962 m) ASL is limited to one hour, without special waiver, if supplemental oxygen is not available and used.

Military flying organizations recognize the need for guidelines to lessen hypoxic exposure, but with their subsequent

incorporation of NVGs, none has investigated how hypoxia might influence NVG-augmented perception or entertained changes in their regulations concerning use of supplemental oxygen. The evidence concerning hypoxia has persuaded Billings (1973) to conclude that hypoxic conditions are less pronounced at lower altitudes, but they exist and may be important under certain circumstances. The importance of the low-level hypoxic environment and NVG-augmented night vision motivated this scientific investigation.

Inducing hypoxia. The effects of hypoxia can be investigated in natural high-altitude field conditions or with any of the following artificial laboratory methods:

- use of a rebreather
- use of a low-pressure chamber
- dilution of air or oxygen by some inert gas such as nitrogen or helium
- artificial pneumothorax
- artificial restriction of the free influx of atmosphere into the lungs (induced blood chemistry imbalance or extraction/dilution of blood cells).

For studies using human subjects, any of the first three techniques is acceptable, but the third is the least expensive and best suited for accurate altitude adjustment when a low-pressure chamber is not readily available. This dilution-of-air method of oxygen deprivation was initially used by Dreyer (1920) but today is far easier and more precise through the development and use of tight-fitting masks, flow regulators, and extremely accurate

gaseous mixtures. Simulation of atmospheric conditions within 20 feet (6 meters) of desired altitude is currently possible.

Method

Apparatus

The experimental apparatus consisted of three major components: the NVGs (AN/PVS-5), the oxygen-metering apparatus used for altitude simulation, and the vision-task apparatus. The NVGs have been previously addressed. They were loaned for this experiment by the 1550th Combat Crew Training Wing (CCTW), Kirtland Air Force Base, New Mexico. The other two items were fabricated.

Oxygen-metering apparatus. Parts for the oxygen apparatus were procured from the Arizona Medical Supply Company, Inc., Albuquerque, New Mexico and the Kirtland Air Force Base Hospital. The equipment and gas requirements were as follows:

- 1 Foregger, facemask, 651105, adult
- 1 Foregger, headstrap, 751004
- 1 Foregger, mask elbow, 701066
- 1 Foregger, non-rebreathing valve, 701055
- 1 Foregger, breathing bag, 503102, 2 liter
- 5 Puritan, regulators, 128314, 0-8 LPM
- 6 Inspiron, prefilled humidifiers
- 1 Size E Cylinder, 25.48% oxygen in a balance of nitrogen
- 1 Size E Cylinder, 19.58% oxygen in a balance of nitrogen
- 1 Size E Cylinder, 17.52% oxygen in a balance of nitrogen
- 1 Size E Cylinder, 15.58% oxygen in a balance of nitrogen
- 1 Size H Cylinder, 100% oxygen
- 1 Size H Cylinder, 100% nitrogen
- 1 Oxygen Analyzer, in-line

The E-cylinder gases were mixed to certified grade, and their analyzed oxygen content was confirmed accurate to within 0.05 percent. When gas was mixed upon delivery, a cardiopulmonary technician confirmed oxygen content accuracy to within 0.2 percent. No subsequent altitude interpolation was deemed necessary as 0.05 percent and 0.2 percent variance in oxygen concentration equates to approximately 77 feet (23 m) and 300 ft (91 m), respectively. The oxygen percentages were adjusted from standard altitude conditions (Table 1) to compensate for delivery at Kirtland Air Force Base, Albuquerque, New Mexico, situated 5,350 feet (1,630 m) ASL.

Vision-task apparatus. The vision tester presented square-wave gratings at varying levels of illumination. One of its components, a calibrated circular neutral density filter, was manually rotated by the experimenter and its position recorded when detection of the square-wave grating pattern was correctly reported. The vision apparatus is shown in Figure 3, and each component is named and its function addressed.

Figure 3. Vision testing apparatus.

Light source: The bandwidth of the 25 watt bulb used as the light source included 450 nm to 820 nm and had an unfiltered luminance of 110 foot-lamberts ($3.77 \times 10 \text{ cd/m}^2$). The spectral characteristics of the light source (Figure 4) were confirmed with a computer controlled monochromator detector wheel and radiometer testing apparatus.

Pinhole: This shield redefined the light source and prevented all source light from serving as target illumination except that passing through its 3-mm center hole.

Lens (1): A plano-convex spherical glass lens was positioned one focal length from the pinhole, thereby collimating the source light.

Lens (2): A precision-optimized spherical achromatic lens with a focal length of 100-mm was positioned to focus the light in

Figure 4. Light source spectral composition.

the center of the circular-gradient neutral-density filter aperture.

Light-tight circular-gradient neutral-density filter (Oriel Corporation, Model Number 2868): A calibrated dial attached externally to the gradient filter indicated the density in the center of the filter's 0.5-inch aperture and allowed precise and repeatable control of density variance. As the light-tight enclosed disc was rotated 285 degrees, density ranged from 0.2 to 2.0 log unit filtration.

Removable neutral-density filter: Fused-silica-substrate metallic neutral-density filters provided a gross reduction in illumination intensity without spectral change during low-level (NVG augmented) testing and upon removal, a higher illumination level for nonaugmented testing. Filters with densities of 3.0, 1.0 (two) and 0.5 allowed 0.1, 10.0, and 31.6 percent source-light-transmission, respectively.

Square-wave grating: Four singularly interchangeable square-wave grating slides provided targets of 14, 7, 3 1/2 and 1 3/4 cpd with either a vertical or horizontal orientation.

Lens (3): A 100-mm precision-optimized spherical achromatic lens was positioned one focal length from the eye at either observation point.

Beam splitter: A 40-mm cube beam-splitting prism reflected 50 percent of the light and passed the remainder.

Unaugmented eye position: The observer's eye was positioned one focal length from the achromatic lens; the forehead and face

were pressed against a secured NVG housing structure identical to that in the NVG viewing position; however, there were no optics or obstructions to interfere with the subject's vision from this position. The grating subtended twenty degrees of the visual field. With the 1 3/4 cpd grating slide in place, an illuminance of 4 cd/m² at this naked-eye viewing position was measured with a photometer.

NVG-augmented eye position: The grating seen through the goggles appeared the same size as in the unaugmented position, subtending twenty degrees of the visual field. A post-NVG-amplified illuminance of 75 cd/m² was measured at this viewing position by the same photometer.

Observers

Six male United States Air Force pilots participated in this study. They were volunteers from personnel assigned to the 1550th CCTW, Kirtland Air Force Base, New Mexico. Prior to participation each observer's most recent annual flight physical examination was reviewed by a Kirtland AFB Flight Surgeon to confirm normal uncorrected vision. Each participant had flown with the NVGs and was familiar with their normal operation. Written permission was received from the Air Force Office of the Surgeon General to conduct this investigation with Air Force personnel at an Air Force installation.

Experimental Design

This study of the effect of hypoxia on NVG-augmented detection/resolution threshold entailed a 2 x 4 x 4 factorial

design. Observers performed square-wave grating resolution tasks both with and without NVGs under four simulated altitude conditions. The four simulated altitudes were sea level, 7,000 feet (2,134 m) ASL, 10,000 feet (3,048 m) ASL, and 13,000 feet (3,963 m) ASL. The square-wave gratings presented the four following frequencies: 14 cpd, 7 cpd, 3 1/2 cpd, and 1 3/4 cpd. In addition, the effects of a brief exposure to 100 percent oxygen were tested after performance at each of the four simulated altitudes.

Procedures

Four of the observers participated in four 70-minute testing sessions conducted over four consecutive days. Each testing session began with the observer seated in a room with the experimenter and apparatus. The room was darkened once the observer's left eye was patched and the observer dark-adapted for 15 minutes. While still in darkness, the observer then breathed from one of the gaseous mixtures for an additional 15 minutes. The mixture was different for each of the four days, and the order of presentation was varied across observers, as shown in Table 2. During the 30-minute dark-adaptation/hypoxic-initiation period, the testing procedures were reviewed. The gas mixture was breathed throughout the experiment and changed to 100 percent oxygen for the final two tasks.

After dark adaptation, the observer was positioned at the non-NVG viewing station. The illumination of each of the four square-wave grating frequencies was individually increased until its

Table 2

Simulated-Altitude Testing Order

| ----- | | | | |
| Subject 5 | - 14.00 cpd | 7.00 cpd | 3.50 cpd | 1.75 cpd |
| Subject 6 | - 1.75 cpd | 3.50 cpd | 7.00 cpd | 14.00 cpd |

each subject viewed was tested once more after each of the four was individually presented. This allowed a quantitative examination of performance decrement attributable to repeated light exposure and possible change in degree of dark adaptation.

The observer then moved to the NVG-augmented viewing station. Grating detection tasks were reaccomplished in the same manner and with the same subject-specific grating presentation orders as used at the non-NVG station. The observer's gas mixture was then changed to 100 percent oxygen. After three minutes, the same tasks were repeated at each viewing station with continuous delivery of 100 percent oxygen. Thirty-four observations were recorded during each test session as shown in Figure 5.

Figure 5. Single-session data gathering.

Depletion of premixed gas required on-site gas mixing for two additional subjects (subjects 5 and 6 in Table 2 and Table 3). An in-line oxygen analyzer was used to monitor mixture balance continuously. The need for cardiopulmonary technician support required that each of these individuals be tested for all altitudes in a single session. Thus, the final two subjects performed the same grating resolution tasks consecutively, e.g.: dark-adaptation/oxygen-deprivation to one test altitude, non-augmented and NVG observations; dark-adaptation/oxygen-deprivation to the second test altitude, non-augmented and NVG observations; dark-adaptation/oxygen-deprivation to the third test altitude, non-augmented and NVG observations; etc. One subject was tested in an ascending altitude order, the other in a descending order. Following their final test altitudes, each subject was delivered 100 percent oxygen and tested once in the same manner as the first four subjects.

Performance Measurement

Both the distance of the luminous source and the inclination of the surface with respect to its direction were kept constant in this investigation. The remaining influence on illumination, the intensity of the light source, was the dependent experimental variable. Changing the light output at its source, however, would have affected its wavelength composition. Thus, the illuminance of the target gratings was controlled through filtering. In this case, neutral density filters allowed a uniform attenuation of light across the spectrum of interest.

Neutral density filters have specified optical densities.

Their transmission percentage is the proportion of light they allow to pass, e.g., a filter that allows 10 percent transmission is referred to as a 1.0 log filter and a filter that allows 1 percent transmission as a 2.0 log filter. In this study, the illuminance of the grating was calculated by recording the density of filtration between the source and the observer. This log scale was retained for performance analysis. Thus, a high log sensitivity performance score means that a subject could resolve a grating orientation with a large amount of filtration; he needed less light for target resolution.

Results

The influence of the modification in the method of altitude simulation and in experimental procedure on visual performance for subjects 5 and 6 could not be assumed to be insignificant, so the data were first analyzed separately for subjects 1-4 and 5-6. There were no major inconsistencies; however, only data from the balanced design with subjects 1-4 who were tested at a single simulated altitude on each of four separate occasions will be reported and discussed.

Figure 6 shows the mean log sensitivity plots both with and without NVG augmentation. A repeated measures analysis of variance was performed on the log sensitivity data. With no supplemental oxygen, there were two highly and one marginally significant main effects: performance deteriorated with increasing grating spatial frequency, $F(3,256) = 856.90$, $p < 0.0001$; improved with NVG augmentation, $F(1,256) = 249.36$, $p < 0.0001$; and tended to deteriorate with increasing altitude, $F(3,256) = 2.24$, $p < 0.080$. (When data from all six subjects was pooled and analyzed, the altitude main effect was also significant, $F(3,288) = 3.3$, $p < 0.02$.) The only significant interaction was between spatial frequency and NVG augmentation, $F(3,256) = 142.53$, $p < 0.0001$.

Linear model analysis of performance without supplemental oxygen revealed that with no augmentation none of the four altitude-specific sensitivity plots differs significantly in slope, but the lowest and highest altitude lines are sufficiently displaced to make them significantly different from each other, $t(126) = 2.16$,

Figure 6. Performance without supplemental oxygen.

$p < 0.05$. This is consistent with the overall analysis of variance that shows the effect of altitude to be marginally significant. However, with NVG augmentation there is no significant difference among the slopes or positions of the four altitude-specific plots.

When supplemental oxygen was delivered after hypoxic exposure, there were two significant main effects: performance deteriorated with increasing grating spatial frequency, $F(3,256) = 993.96$, $p < 0.0001$; and improved with NVG augmentation, $F(1,256) = 188.89$, $p < 0.0001$. The only significant interaction was between spatial frequency and NVG augmentation, $F(3,256) = 176.86$, $p < 0.0001$.

Figure 7 shows the mean log sensitivity plots both with and without NVG augmentation after subjects received 100 percent oxygen for three minutes subsequent to an altitude simulation. Performance with NVG augmentation for the 14 cpd grating was not measurable because even with full unfiltered illumination no subject resolved the grating orientation. Linear model analysis revealed that without NVGs, none of the four sensitivity plots following altitude simulation has a significantly different slope, but the second lowest (7,000-foot) and highest (13,000-foot) altitude lines are sufficiently displaced to make them different from each other, $t(94) = 2.13$, $p < 0.05$. Again, with NVG augmentation there is no difference among the slopes or displacements of the altitude-specific post-test plots.

Figure 8 shows performance means as a function of time. The balanced nature of the experimental design allows such subject integration. Comparison of pre- and post-100-percent-oxygen

Figure 7. Performance with supplemental oxygen following test altitudes.

performance reveals a difference of 0.19 log sensitivity (2.03 versus 2.22) between naked-eye oxygen-deprived and oxygen-supplemented performance. However, a difference of only 0.02 log sensitivity (3.93 versus 3.95) is observed between NVG-augmented oxygen-deprived and oxygen-supplemented performance.

Finally, a direct altitude-specific comparison was made across subjects and gratings for each of the four testing sessions. Each subject's 1st and 2nd observations (Figure 5) were averaged and

Figure 8. Performance means.

compared to his averaged 18th and 19th observations, 3rd and 4th to 20th and 21st, 5th and 6th to 22nd and 23rd, etc. The results are shown in Table 4. In 52 of 64 cases, less illumination was required for oxygen-supplemented naked-eye resolution.

When examined by altitude, incidence of performance improvement logically increased with ascent; 69 percent of the

Table 4

Changes In Mean Illumination Levels Required For Resolution After Supplemental Oxygen.

| Without NVG | | | | | |
|-------------------|-----------|-------|--------|--------|-------|
| | Sea level | 7,000 | 10,000 | 13,000 | Total |
| Less illumination | 11 | 13 | 14 | 14 | 52 |
| No change | 0 | 1 | 0 | 1 | 2 |
| More illumination | 5 | 2 | 2 | 1 | 10 |
| With NVG | | | | | |
| | Sea level | 7,000 | 10,000 | 13,000 | Total |
| Less illumination | 6 | 6 | 5 | 5 | 22 |
| No change | 1 | 0 | 3 | 0 | 4 |
| More illumination | 5 | 6 | 4 | 7 | 22 |

Note: There are 12 trials for NVG viewing at each altitude rather than 16 because the 14 cpd gratings could never be resolved with the NVGs.

sea-level post-oxygen resolutions were made with less illumination than in the unsupplemented sea-level condition, whereas 88 percent of the 13,000-foot post-oxygen resolutions were made with less illumination than in the preceding 13,000-foot oxygen-deprived condition. In contrast, no such post-oxygen improvement is evident with NVG augmentation; with supplemental oxygen there was an equal likelihood that resolutions required more or less illumination.

Discussion

Hypoxia differentially affected unaided and aided performance, as evident from both the graphic plots shown in Figures 6 and 8 and from the various statistical effects. Overall, the lack of oxygen significantly degraded unaided but not NVG-augmented performance. As shown in Figure 9, the naked-eye tests were done in scotopic, rod-dominant conditions. Only with the two higher-frequency gratings did illuminance levels required for resolution approach a mesopic condition. In contrast, the NVGs provided an amplification

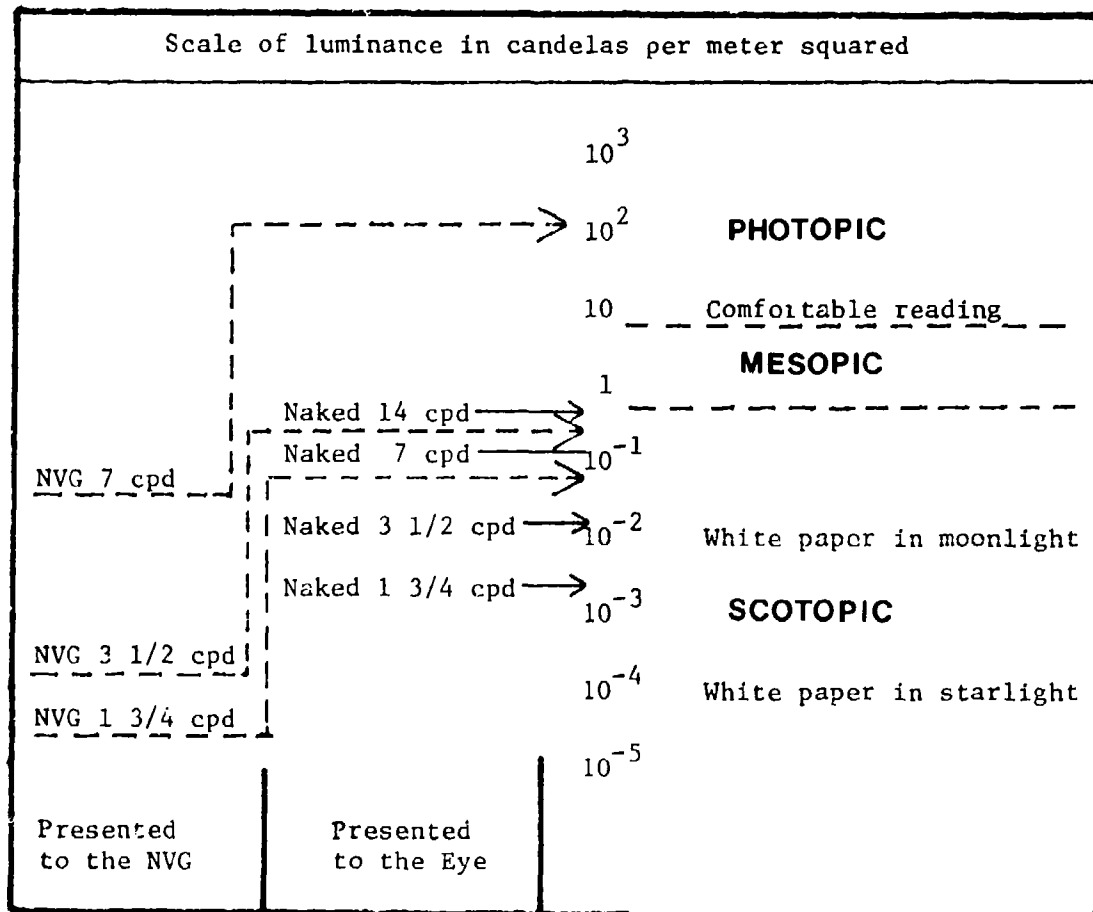

Figure 9. Square-wave grating mean luminance levels.

of illuminance and boosted two of the three NVG-augmented scotopic levels to photopic and borderline mesopic values.

Grating resolution performance was also differentially affected by hypoxia with and without augmentation. In neither the unaugmented nor the NVG condition was there an altitude-by-grating interaction; however, the significant goggle-by-grating interaction is evident in Figures 6 and 7. The slope of the increase in illumination required with the NVGs for resolution with increasing spatial frequencies was 50 percent steeper than that for unaided vision. The overall increase in required illumination associated with increasing spatial frequency, shown in Figure 9, is consistent with McFarland's (1953) findings.

The reasons higher spatial frequencies require more illumination are twofold. First, rods have lower resolving power than cones. In low illumination, there is less light to stimulate the rods, and no help from the cones is available until the illumination is in a mesopic range. Second, when the pupil opens in low illumination, target definition suffers, thereby requiring more light or targets of lower spatial frequencies for resolution. A grating-frequency main effect has been found in most low-level illumination studies that likewise show increasing deterioration with higher spatial frequencies (Campbell & Green, 1965).

Figure 9 shows that the NVGs presented to the observer a grating with 100 to 1000 times the average illuminance of the filtered source. Of particular note is the fact that when the square-wave grating frequency was 7 cpd, performance with the

goggles was only slightly (though consistently) better than without augmentation. This shows the tradeoff involved in goggle augmentation; the NVGs degrade resolution, but this is more than counterbalanced by the increase in illumination. However, with the 14 cpd square-wave grating, the illumination amplification could not make up for the resolution lost in image processing. When the 14 cpd grating was presented, the observers reported only a very bright field; none resolved the grating.

Naked-eye performance improved with supplemental oxygen. Table 4 shows that with 100 percent oxygen there was a consistent improvement over any simulated altitude condition. As in many of the previously cited vision investigations, the oxygen requirements of the visual sensory system are sufficiently high that even slight deficiencies result in performance degradation. But with the frequencies tested in this experiment, NVG-augmented performance did not suffer in oxygen-deprived environments up to 13,000 feet (3,963 m) ASL.

The maintenance of dark adaptation was checked in this experiment. Figure 8 graphically shows that dark adaptation was not compromised during unaugmented testing; the ratio of instances requiring more illumination versus less illumination on 9th trials versus 1st trials across sessions was 9 to 7. However, there was adaptation loss from NVG-augmented viewing; more illumination was required for naked-eye resolution in 11 of 16 post-oxygen-supplemented NVG observations.

Lastly, the subject's habituation to Kirtland AFB,

Albuquerque, New Mexico, (5,350 feet ASL) might influence generalization to those not so acclimatized. The effect of hypoxia on resolution performance observed in this experiment may underestimate the hypoxic vision decrement of observers acclimatized to sea level.

Conclusions

This experiment answered three questions of interest to NVG users. The visual environment produced by NVG augmentation does not seem to necessitate adjustments in flight restrictions or search procedures other than consideration of target size. Moderate hypoxia did not significantly affect the NVG-augmented square-wave grating resolution acuity of observers acclitized to 5,350 feet (1,630 m) ASL. Up to 13,000 feet (3,962 m) ASL there was no significant degradation in target resolution performance. Without augmentation, however, there was a significant difference between resolution performance at sea level and at 13,000 feet (3,962 m) ASL. The latter altitude necessitated a significantly higher target illumination.

In both aided and unaided conditions the illumination needed to resolve the target was influenced by its spatial frequency; higher frequency targets required higher illumination. However, the NVG's overall performance superiority was limited to spatial frequencies of 7 cpd and below. In no case was a subject able to resolve a 14 cpd target with the NVGs. As a result the naked-eye acuity at the highest spatial frequency tested was superior to that with augmented illumination but reduced resolution.

Finally, there was consistent improvement in unaided resolution performance after a three-minute exposure to 100 percent oxygen over any of the simulated altitude conditions. The degree of improvement logically increased with ascent. However, supplemental oxygen did not consistently improve NVG-augmented

performance. With supplemental oxygen, there were equal occurrences of performance improvement and deterioration.

Most importantly, this study revealed no hypoxic performance decrement up to 13,000 feet (3,962 m) ASL with NVG augmentation. The investigation shows no reason to revise current flying or search altitudes directives. The likelihood that oxygen supplementation would improve NVG-aided resolution acuity up to 13,000 feet (3,962 m) ASL is not indicated by this study.
